PREFACE

STATEWIDE

PREFACE

If planning and financing of multi-modal transportation systems is to be effective, it is necessary to identify the extent of mobility of all population groups in the state. Once the geographic distribution of various mobility groups in the state is identified and defined, rational planning of transportation systems can proceed. The allocation of present and future transport development funds must emerge from sound decision making processes derived from transportation need and existing service.

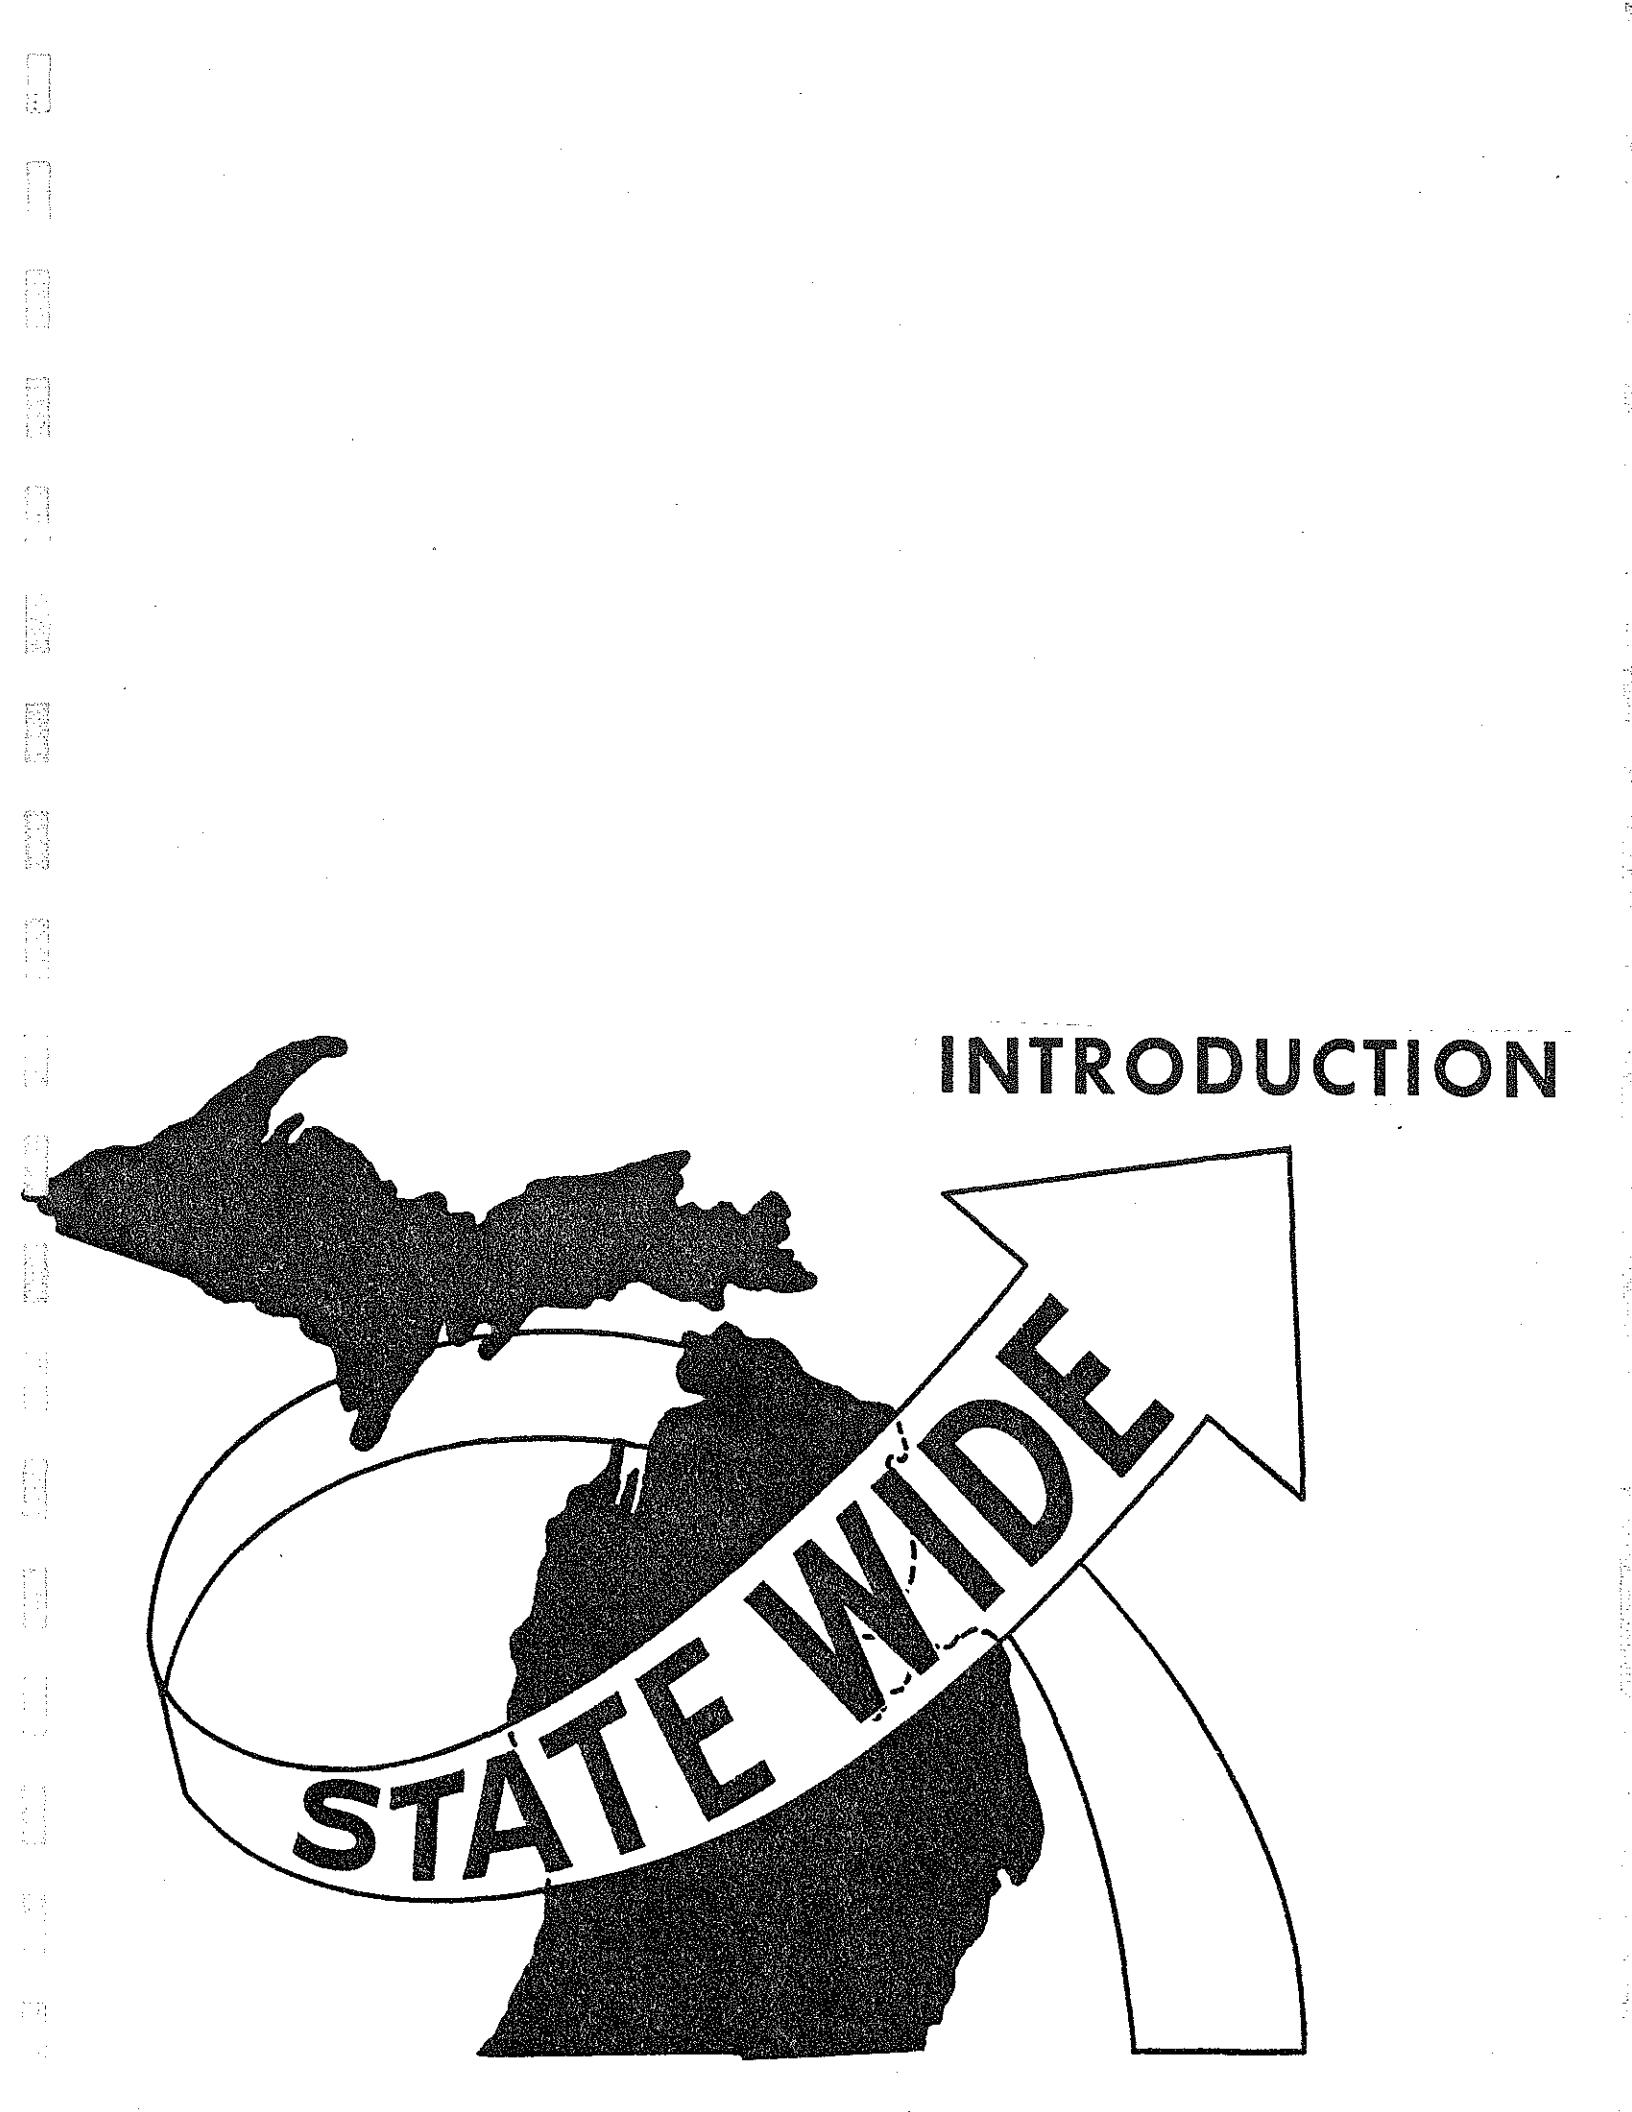

The current transportation modeling systems are built to forecast demand for travel based on predicted levels of population and surrounding population. Due to changing social priorities, as the result of the political process, there is a need for the transportation modeling to be flexible if statewide and regional goals are to be effectively met. This report deals with the discussion of mobility impact variables in the application of the statewide transportation modeling system to changing needs and priorities. The statewide mobility analysis concept is an outgrowth of the following reports: Social Impacts of Alternative Highway Plans on Public Facilities, Statewide Socio-Economic Data File and Statewide Public and Private Facility File. The first report deals with a program called "Proximity Analysis", which can be used to determine the availability or accessibility of each mobility and its spatial relationship to the socio-economic and transportation facilities inventory. This technique is most often used in the analysis of social impact of alternative transport development

programs and can also be used to identify opportunities to increase mobility. The development of statewide mobility analysis process is composed of two major categories:

- (1) Socio-economic factors related to mobility
- (2) Transportation facilities related to mobility

This report will discuss the development and analysis of a potential statewide mobility index using these two basic elements.

INTRODUCTION

STATEWIDE

INTRODUCTION

Mobility is a relative concept, defined by societal goals and objectives which change over time. Ideally, mobility is a fundamental right, expressed in the "commerce" clause of the U.S. Constitution. Mobility may be defined as a latent function of national goals and priorities to maximize individual accessibility to opportunities to increase national productivity. Operationally, mobility is a function of the socio-economic status of the individual and the geographic distribution of socio-economic wealth. Mobility or the change in mobility characteristic of population groups for which several governmental agencies have been delegated responsibility to enhance. The enhancement of mobility or increasing the ease of accessibility to opportunities may often be a primary goal of many transportation agencies.

The planning process must establish a procedure which will be able to delineate varying degrees of population mobility at the statewide and regional level. Regional distribution of multi-modal transportation opportunities and their relationship to socio-economic characteristics may also be identified so as to determine possible areas of latent demand.

Due to changing priorities in recent years, the socio-economic differences in the opportunities to be mobile have been illuminated by increasing dissatisfaction in deficient areas. Many of these issues have often been related to the lack of accessibility to opportunities. These opportunities are often listed as

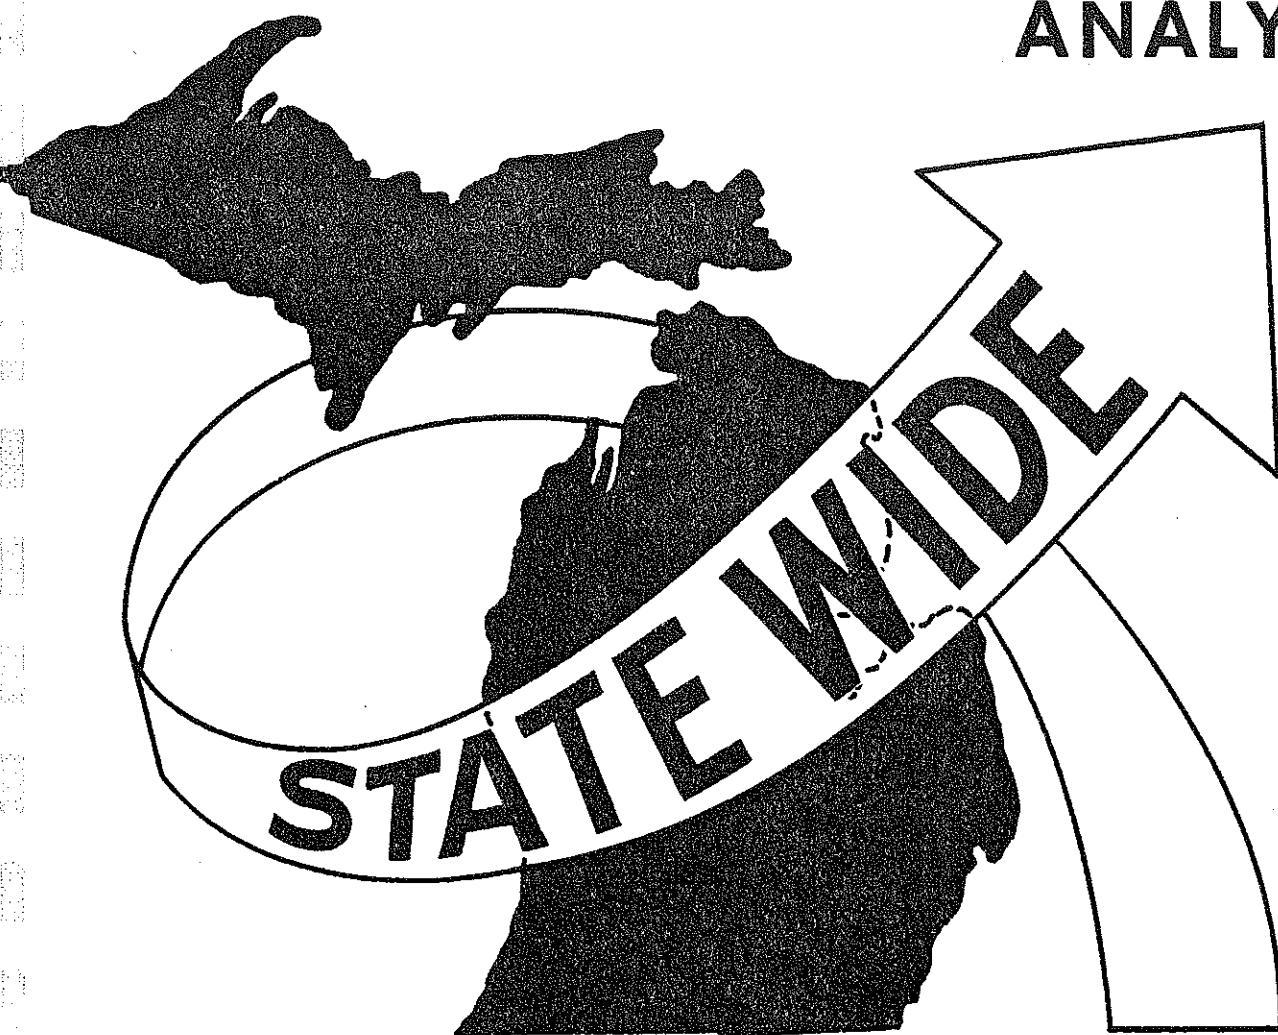

employment, health facilities, recreational facilities and educational opportunities.

Since mobility is important to the basic survival and subsistence of the American population, the agencies whose primary functions are the enhancement of transportation opportunities should be concerned with the processes of evaluating different mobility opportunities, their distribution, and factors which hinder their distribution. To fulfill these primary directives, a statewide mobility analysis system has been developed. The mobility analysis components discussed in this report are part of the statewide transportation modeling system which possesses the following essential qualities:

- (1) The ability to be continuously updated to provide up-to-date information of changing mobility factors.
- (2) Mobility impact analysis should be able to be completed quickly, so that impact information keeps pace with the process of planning alternative courses of action and impacts of different alternative can be measured.
- (3) The mobility indicators would provide information requested by the Federal-Aid Highway Act of 1970, which requires that the evaluation of each proposed Federal-Aid Highway project must include an analysis of the social effects of the projects.

MOBILITY INDEX

ANALYSIS

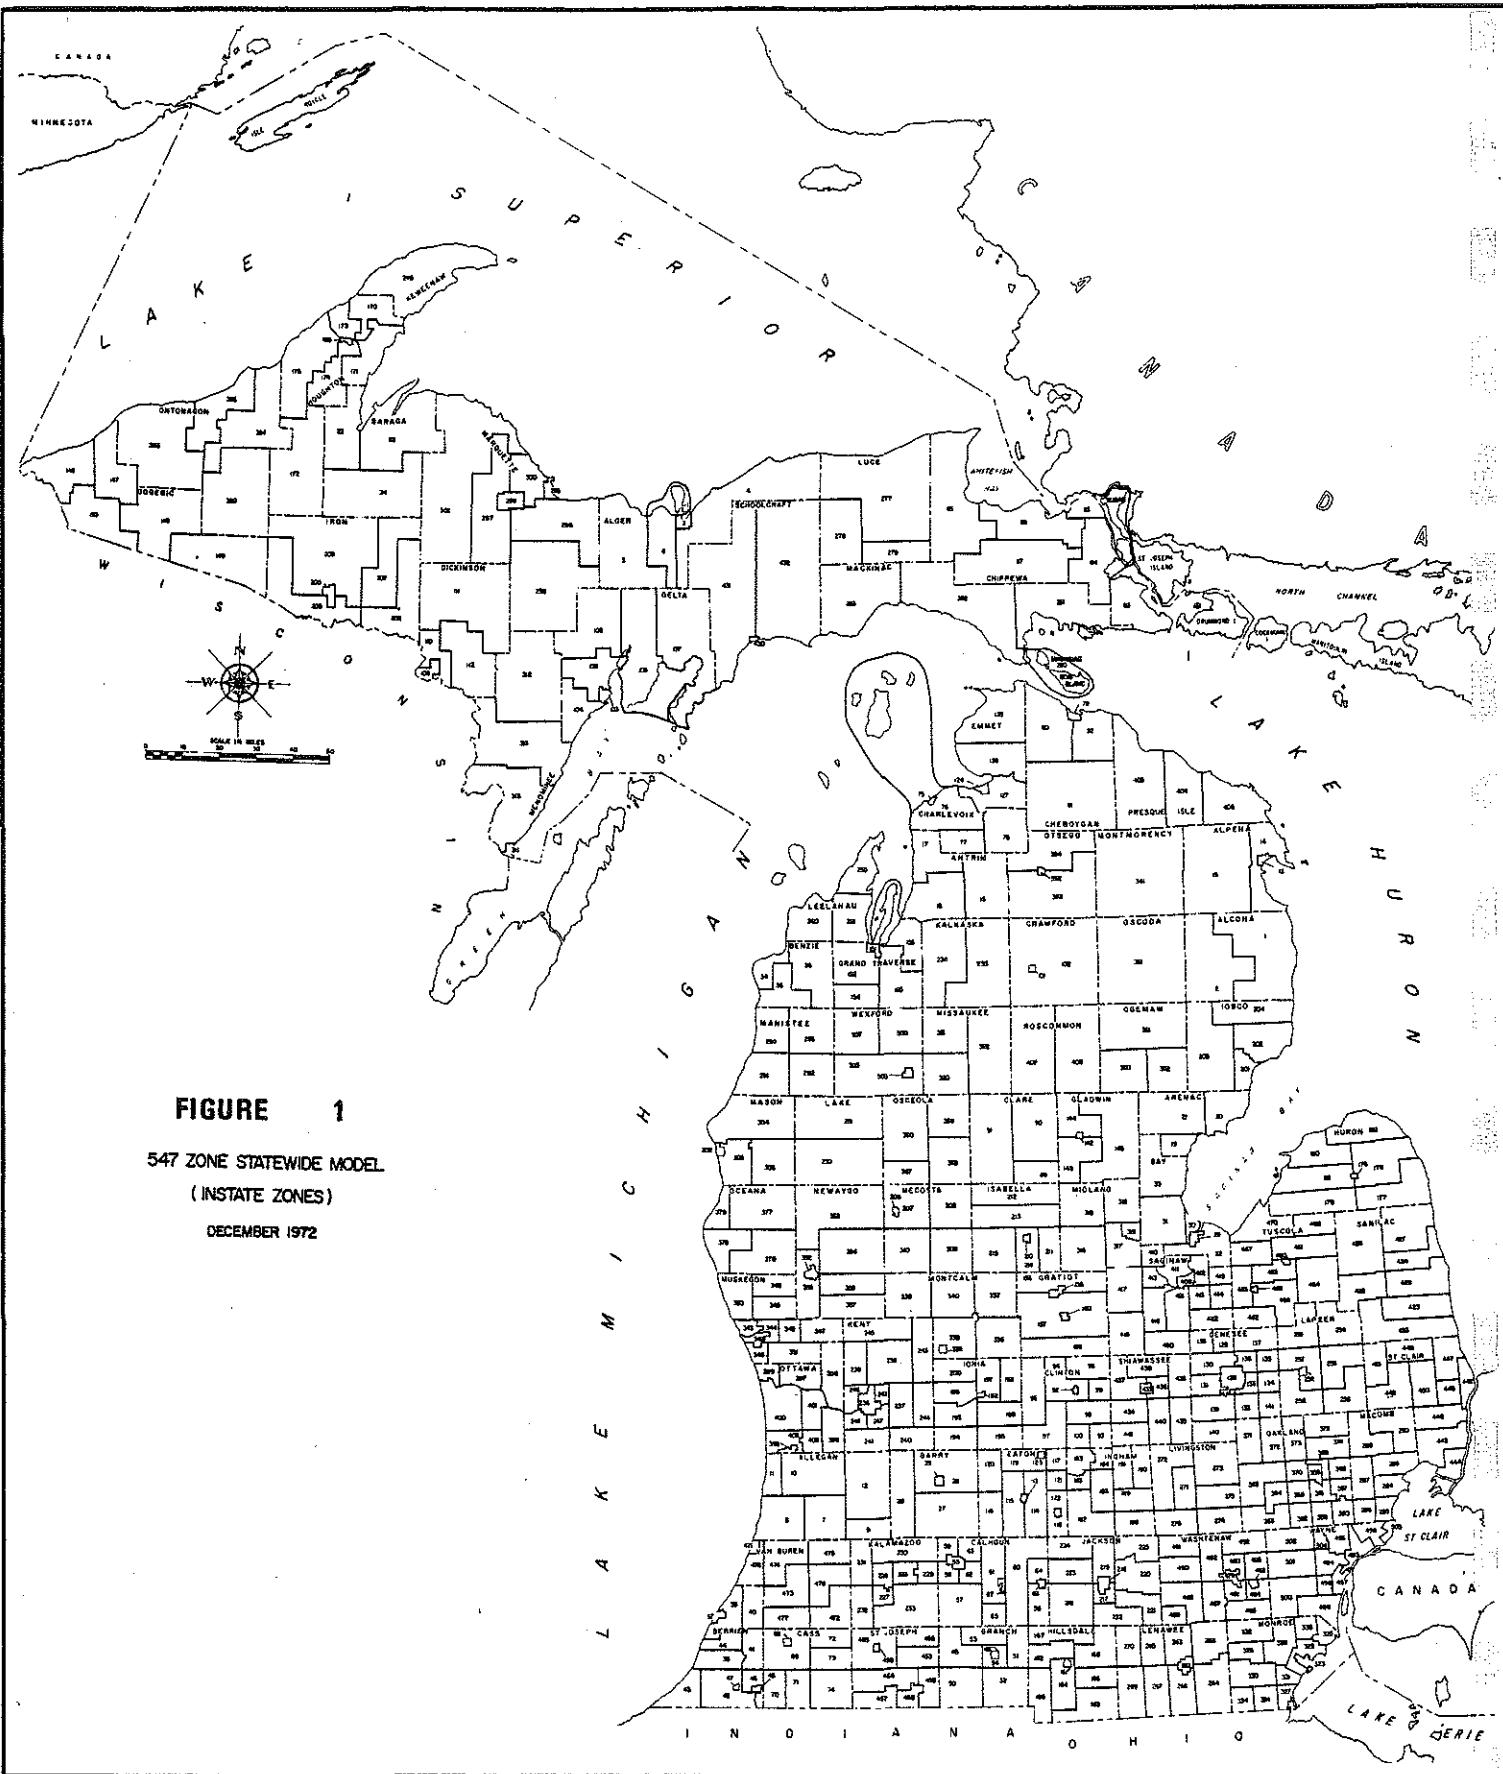

MOBILITY INDEX ANALYSIS

The Statewide Mobility Indices System is an outgrowth of the Statewide Transportation Modeling System. The modeling system is composed of three major data components: The Statewide Socio-economic Data File, the Statewide Transportation Network and the Statewide Public and Private Facility File. These three files are defined in the modeling system as representing society. Each file is extensive and therefore responsive to the information needs of the varying goals of each user. Each of these data files then provide information which can be integrated into an analysis to aid the transportation planning process. The Statewide Model divides the state into 508 analysis zones as shown in Figure 1 and these are the zones to which the data files are summarized.

The Statewide Public and Private Facility File shown in Figure 2 contains information about the physical environment. Selected elements of this file such as the bus, rail, truck and port facilities deal with mobility considerations which will also be integrated into the statewide mobility analysis system.

The Statewide Transportation Network link file contains the physical description of each highway segment or link. This second file was created by developing a program referred to as "automated data-bank interface" which allows the travel modeling process to access and summarized information residing in any of the following department files:

- A. Trunkline Vehicle-Miles Master File
- B. Michigan Highways Yearly Sufficiency Rating File
- C. Accident Master File
- D. State Trunkline Control Section Log Record File
- E. State Trunkline Needs File

Combinations of data from the above files make up the final highway network line file appearing in Figure 3.

The third component of the Statewide Transportation Modeling System is the Socio-economic File. This file contains 888 pieces of selected census information concerning the overall population characteristics within that zone from the 1970 census of population and housing. The socio-economic file can be used to locate special groups of people, but even more important, the relationship of these people to existing facilities or opportunities. Selected information from this file is shown in Figure 4.

Majority of the variables used in this report were obtained from the socio-economic file and the public facility file. The socio-economic file is accessible through the Statewide Information Retrieval Program either from remote terminal or on site. Specific information can then be obtained for each zone. The socio-economic file can be continuously updated to accommodate new material.

Information retrieved from the socio-economic file may be graphically displayed on an outline of the State of Michigan through the use of a line-printer mapping program developed by the Laboratory for Computer Graphics and Spatial Analysis, Harvard Center for Environmental Design Studies, Harvard University. The program is called SYMAP. An example of symapping is the mean income map of Michigan appearing in Figure 5. All data generated from the socio-economic or public facility file may be graphically displayed in a similar manner.

Another method of analysis of information generated by the use of mobility indicators is through the proximity analysis process. The proximity analysis program attempts to define the relationship of special groups of people to existing facilities or socio-economic factors. In general, the process includes a zone-to-zone driving-time matrix (used in the Statewide Transportation Model) to accumulate socio-economic information within specified driving-time bands for user-supplied facilities. For the details of this process, the reader is referred to the report "Proximity Analysis: Social Impacts of Alternate Highway Plans on Public Facilities". For actual applications of proximity analysis, the reader is referred to the following publications:

1. "Proximity of Population to General Purpose Hospitals"
2. "Proximity of Airports with Scheduled Service to Population"
3. "Impact of Transportation Systems on the Proximity of Airports and Labor force to Industrial Parks".

A more detailed discussion of this process will follow in the transportation resource component section.

The basic structure of the mobility analysis system in this report deals with two components. They are the socio-economic component and the transportation resource component. The integration of the socio-economic component and transportation resource component could make up a single value for statewide mobility at the 508 zone level. A statewide mobility indicator system can systematically be generated if states develop transportation modeling systems similar to Michigan's.

The following sections will describe the application of the Statewide modeling system and the development component systems and their various factor groupings in depth.

SOCIO-ECONOMIC COMPONENTS OF MOBILITY

SOCIO-ECONOMIC COMPONENTS OF MOBILITY

The typical statewide mobility index developed in this document consists of two basic components: The socio-economic component and the transportation resource component. Together the components will provide measures or indicators of mobility at the zonal level for the State of Michigan. For example, a zone may have a high socio-economic propensity to be mobile, but lack alternative modes of transportation such as a bus system. Therefore, the socio-economic indicators may show selected areas as being more likely candidates when allocating transportation resource dollars. This section of the report deals with the development of the socio-economic component.

The following list might make up a set of typical socio-economic factors which identify the existing mobility characteristics for each zone in the state:

1. Carless households
2. Elderly
3. Handicapped
4. Youth
5. Income level
6. Density
7. Auto ownership
8. Family size

All of the data in each group is available from the statewide socio-economic data file.

These variables describe those people which may be identified as transit-dependent or immobile because of a lack of personal means of transport. This data provides insight into the relative mobilities of different socio-economic groups at the statewide level. It is of great importance to determine the location of mobility variations within specified homogenous groups throughout the state.

At the zone level, carless households exhibit a different type of mobility than car owning households. The Nationwide Personal Transportation Survey in 1969-1970 identified 80% of the carless families living in central cities and 20% living in outlying suburban areas. Members of the carless group take one trip less per person than do people with the same income with one car. Below the poverty level, the carless depend on public transportation intensively. An income rises in these households, there is more ride sharing, less use of public transportation and car borrowing. Carlessness is associated with reduced participation of shopping and leisure trips, and inconvenience. The 1970 Housing Census identified 322,589 households in Michigan as being carless.

The elderly indicator consists of all people of the age of 65 and older per zone. The aged have various constraints on mobility; most of these constraints are related to income and

physiological factors. Age-related physiological, psychological and social changes interact with transportation changes and disproportionately increases the hazards and discomforts of traveling from one place to another. As people age, sensory acuity diminishes, strength and agility decline, and responses become slow. Perceptual-motor changes decrease the ability for a correct response to complex stimuli. Body balance becomes less secure when walking and standing, with tendencies to lose equilibrium.

The main concern for increasing the mobility of the elderly as a group is not always for humane factors but for its economic value to society. Transportation supports the individual's capacity for independent living, and thus assists in postponing or avoiding institutional care. In analyzing the travel behavior of the elderly, there is a substitution of work trips to shopping and recreational trips as being more important.

The following counties in Michigan contain a large portion of the elderly population: Gogebic, Iron, Dickinson, Montmorency, Oscoda, Alcona, Roscommon and Lake. Considering the income and physiological constraints of the transportation needs of the elderly, obstacles to adequate provisions for their needs are relatively greater in the rural areas than in urban area.

The handicapped are the most neglected in a transportation system where the prevalence of stairs obstructs effective use of the existing system. Again, many handicapped receive small incomes and the majority are not licensed drivers. The handicapped category encompasses a population of both physical and mental disabilities

and an increasing number of multiple disabilities. The greatest impediment to mobility is the stairs and steps of transport system, designed with little attention to people with ambulatory problems. The vertical element of the transport system, coupled with the corresponding vertical element of buildings, further limits employment opportunities, as well as transportation opportunities. Trips for recreation, shopping and visitation are also limited by these factors.

The design needs of the handicapped are varied. For example, the multi-handicapped need individualized services and facilities in terms of vehicle speed, interior vehicle design and mechanical supports. Obviously, the variation of needs hinders the use of a standard type of input into the main transport system.

Any planning process should identify groups who are ineligible to drive because of age and therefore depend upon others for transportation. Eligibility to drive affects the trip-making in many households. Trip-making of children and adolescents are further constrained by socio-economic factors. It must be noted that children and adolescents are a substantial proportion of the persons who occupy the lowest income households. The children of the poor will exhibit the travel behavior of the group. Travel by the young increases with rising family income.

Indicators which identify the location of low and high income groups have important connotations for trip behavior. The lower income groups are often more dependent on public transportation whereas the high income group may rely on air travel. The greatest

reason for increasing the mobility of the poor is so that they may have a better opportunity for socio-economic gains. This category will overlap the variables of the elderly, the children and the handicapped. For the most part, the poor do have cars available for some of their trip making. But poor car owners may often have unreliable cars for their trip needs.

The work trip may consist of public transportation, ride-sharing or car sharing. Because of the lack of the economic means to support and operate a car, the poor may take fewer trips for shopping and recreation. Symapping has been used to portray the spatial distribution of the poor or families with income under 5,000 (see Figure 6).

The indicator system also provides measures of mobility based on population density. John B. Lansing, in his study of Residential Location and Urban Mobility,¹ points out the association of population density with automobile ownership. The level of automobile ownership is higher in areas of low density than areas of higher density. Density of the area has a strong effect on the choice of mode. The density indicator, zonal population per square miles of the area, not only indicates suburban, rural or urban population, but will indicate where the higher trips are made. Low density areas with high auto-ownership will indicate more trip-making. This category may also be included in the household mobility factor.

The number of cars per household provides a relative indication of the level of trip making among households. The data was derived

from the 1970 Census of Housing Detailed Housing Characteristics and also available on the socio-economic file. The data was gathered according to the number of families with no cars, 1 car, 2 cars, and 3 cars per household. According to the census, Michigan has 1,296,177 households with 1 car, 874,132 households with 2 cars, and 160,157 households with 3 cars or more. The mobility index reflects the average number of cars per households for each zone.

The National Personal Transportation Survey uses this variable to describe car-deficient households. Car deficiency is defined as households containing 4 or more members and having one car available. Other studies on modal choice, such as "The Automobile Use in Patterns in New York City,"² indicate longer distance travel in households of two cars and more. Data on availability per household provide insight for car deficiency, car saturation and modal split consideration. This same socio-economic variable could also be used as a transportation resource component.

Household size data is also a statistic similiar to auto ownership which could provide indications of trip-making among families in a zone. The mobility literature draws connections between higher trip-making and more household members per family. The older the household members, the more trips are needed. John B. Lansing's study on "Residential Location and Urban Mobility", reports the relationship between families with two or more adults and car ownership. A Study on Passenger Transportation³ directed

attention to a decline in trip production per capita with each increase in family size. The study indicates a larger number of trips are generated by each increase in family size, but the rate of increase generally declines. The indicators system provides average household size per zone.

This variable would be very useful in studies in car ownership, trip generation and vacation trip studies. The household on trip making as well as other behavioral factors relevant to population movement. The analyst could attempt to explore alternatives optimizing this factor.

These socio-economic components of the mobility indicator system can all easily be manipulated for various research and statistical uses in mass transit behavioral surveys for future adaption of the Statewide Transportation Modeling System. The details of such a sample mobility indicator analysis appear in Appendix A.

TRANSPORTATION COMPONENTS OF MOBILITY

STATE WIDE

TRANSPORTATION COMPONENTS OF MOBILITY

The transportation resource component, which is the second major component of mobility, addresses the distribution of transportation facilities in the state. In this report, the transportation resource variables consider only those facilities in which all purposes of trips are generally made. Bicycling, trucking, water and recreational vehicles were excluded because they are primarily used for single-purpose travel (work, leisure, shopping, etc.). The transportation resource components can be used to provide a statewide view of the existing distribution of transportation resources. The system is designed to permit expansion of the index by adding selected transport facilities in the future.

The transportation resource component further allows any transportation agency the opportunity to more completely address the issues related to the mobility of all citizens in the state. While the socio-economic component mainly exhibits the status or conditions of people on statewide basis, the transportation resource component will portray deficiency or saturation of resources.

The following list is the set of transportation facilities used for the mobility analysis in this report.

- (1) Auto Ownership
- (2) Bus Terminals (Intercity)
- (3) Rail Terminals

(4) Airports

(5) Ports

In this section the first variable, dealing with auto ownership, will be treated differently than the others. This is due to the fact that in most analysis the total number of autos or the ratio of autos to persons is sufficient to reach a reliable decision. With the four types of transportation the analysis often required that management know the spatial relationship of these resources to the person being served.

The major factor groupings are composed of several descriptive variables which indicate mobility. Most of the data is available from the Public and Private Facility File.

Michigan's transportation resource is heavily dominated by the automobile. The 1970 count of vehicle registration was 5.2 million.

Auto ownership data from the Statewide Transportation Modeling System consists of the number and distribution of auto registration on a zone level. Using the socio-economic file to obtain population, auto-to-person ratio per zone has been obtained; this data is available in Appendix B.

The bus transportation facilities constitute a much smaller input to the entire system. The accessibility of citizens in Michigan to bus service will be documented in the final paragraphs of this section and also in Appendix B. There are presently 23 intra-urban bus operations in Michigan. The southeast Michigan

area has the highest use in public transportation, the total annual passenger ridership in 1970 being 123.5 million. Also included in this factor is data on some taxi services around the state.

The state's 12 inter-urban lines account for around 16 million vehicle miles. A listing of each station is available from the facility file.

The railroad terminal variable was included to provide a distribution of both past and present rail facilities which have the potential to be converted to passenger service. Presently there is only one operating passenger route with the possibility of service expansion during the next few years. A listing of all railroad stations inventoried is available for anyone wishing to complete stateion by station analysis.

As mentioned previously, the public facility file provides a listing of all county, private and public air fields. The index provides insight for future studies on commuter work-travel and modal split considerations.

The previous section investigated the socio-economic characteristics of individual zones. By contrast, the travel resource component of mobility deals with the degree of accessibility of each zone to various modes of transportation-- particularly in the case of air, rail, bus, and port-- and the availability of automobiles to the residents of a zone. One tool used to measure this accessibility is Proximity Analysis, a computer program developed in Michigan to measure the concentration of facilities

socio-economic characteristics about areas of interest.

As a by-product of the Statewide Traffic Forecasting Model, a matrix is created which gives the driving time from each zone to every other zone along the shortest-time path, using speeds on highway links derived from MDSH&T speed studies. The times are calculated between zone "centroids", or approximate centers of population. With this information, one can accumulate the number of bus terminals, or airports, or rail terminals within an hour's driving time of each zone of Michigan.

Two facts should be noted here. First, zone-to-zone travel times do not include so-called "terminal times." Terminal time is the average additional time needed to reach one's ultimate destination once the zone centroid is reached. For example, a person driving to Detroit Metropolitan Airport must spend extra minutes in finding a parking place and walking to the terminal.

Second, the process does not subdivide zones. If a zone contains three bus stations and the zone centroid happens to lie within 30 minutes' driving time of zone 100, then all three stations are assumed to lie within 30 minutes of zone 100.

For example, consider the following schematic of some of the shortest-time paths from zone 344 in Muskegon County:

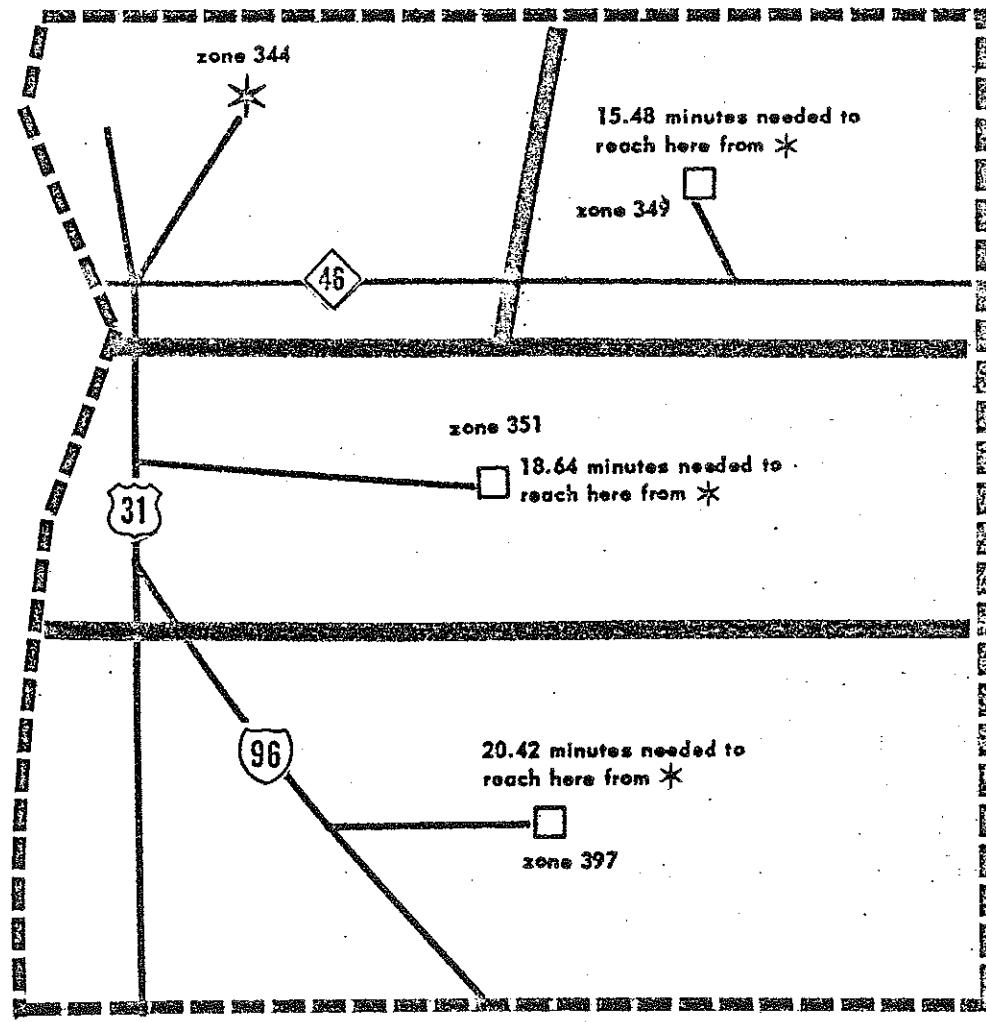

FIGURE 7: PORTION OF TREE

The boxes denote centroids, and the links connecting centroids to the highway system are called "centroid links". Centroid links need not physically exist as highways, but the time and distance assigned to each reflects the average time and distance needed to access the highway system from various points within that zone.

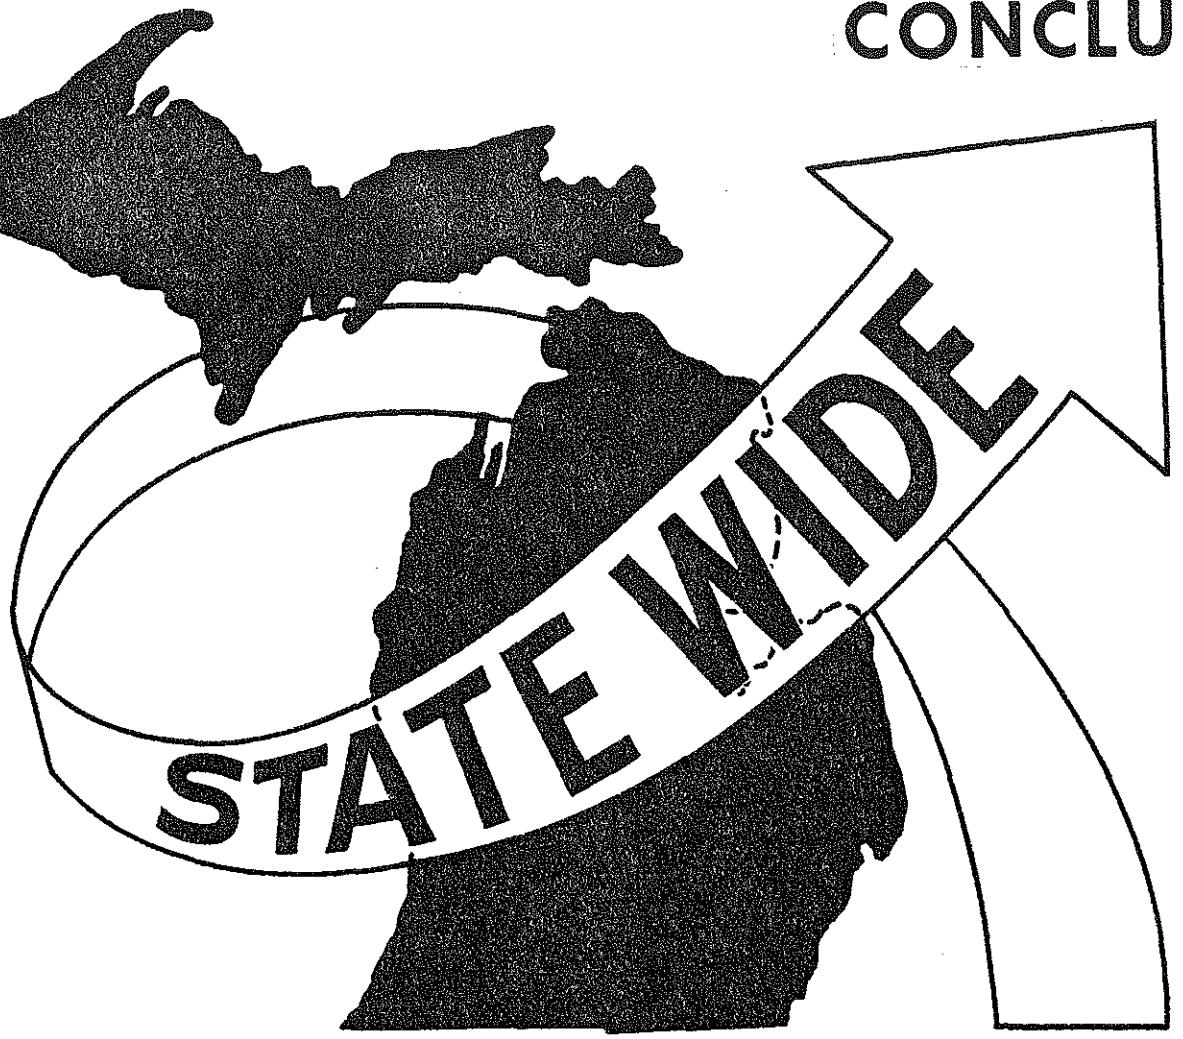

If a user desired to know how many intercity bus stops, say, are within twenty minutes' driving time of zone 344, all the stops within zones 349 and 351 would be accumulated, regardless of their geographical distribution within the zones. By the same rule,

none of the stops in zone 397 would be accumulated, because the centroid of zone 397 lies more than twenty minutes away from zone 344. This simplifying rule has apparently not significantly detracted from the accuracy of the results of the Proximity Analysis process in many interdepartmental applications. If extremely delicate calculations must be made, it is possible to create a "zone" at each facility of a given set. In that case, no approximation or simplification need be made.

Finally, it is possible to test the effects of alternative transportation plans on the degree of accessibility of various socio-economic groups to public transportation. If desired, distance or driving cost can be used as a measure of zone separation instead of driving time.

In this analysis, the program was instructed to scan sixty minutes around each zone of Michigan and to determine the number of bus stations, airports, rail stations, and ports which occur within that radius. In addition, the number of households having at least one automobile. The results for each zone are printed in appendix B. It should be mentioned that a user may elect to investigate driving-time bands other than 60 minutes; the program allows up to ten time bands to be specified.

CONCLUSION

CONCLUSION

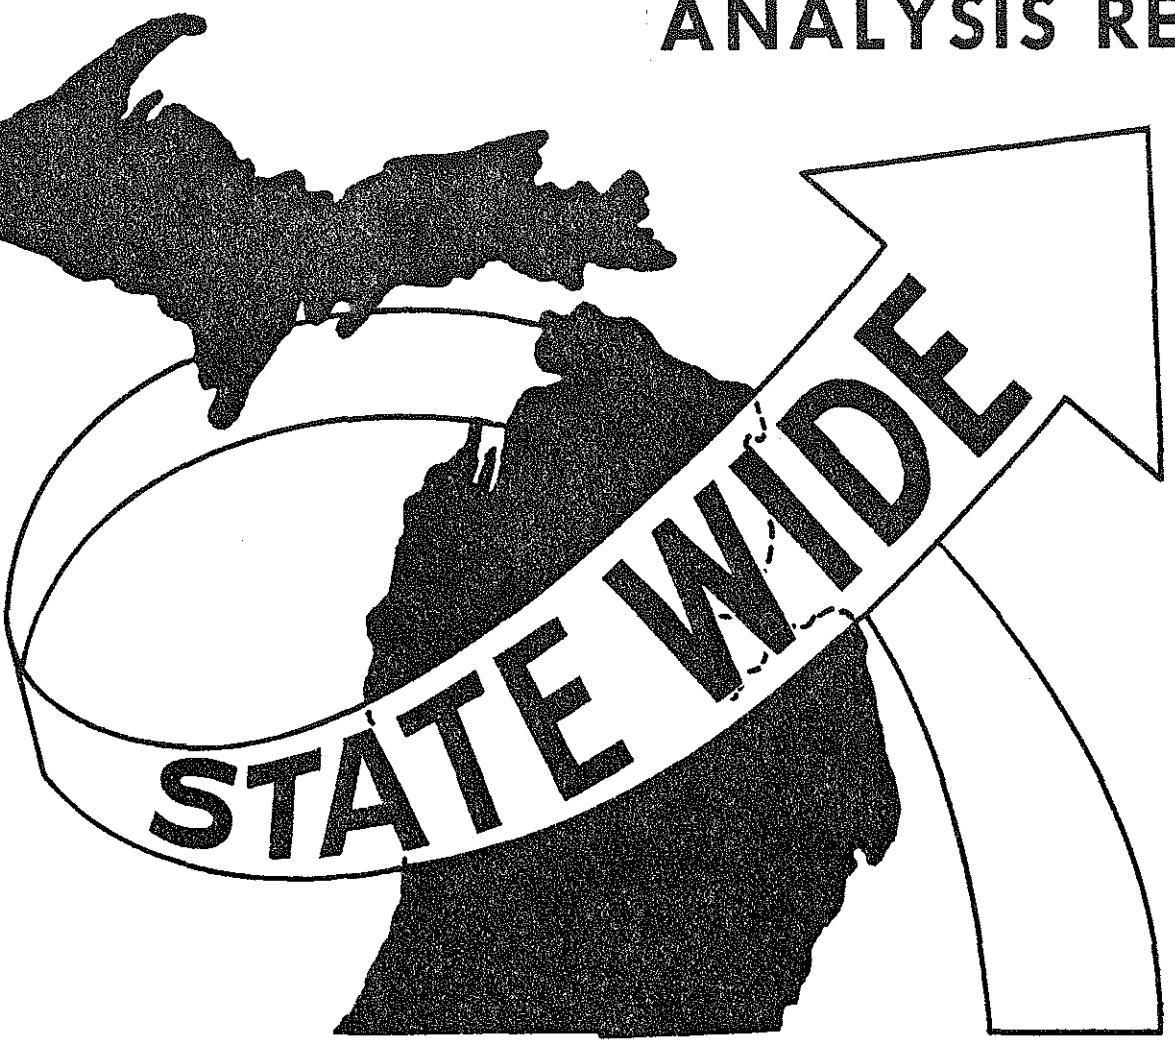

Mobility indicators can be of considerable value in assessing current and projected mobility conditions, as well as the efficiency and effectiveness of public agency plans and programs. One major use lies in the possible development of a regularly-published account showing where accessibility to opportunities has progressed or decreased as the result of capital spending. Another lies in strengthening of the planning process itself by being able to monitor the impact on mobility. A third area of possible application involves the more rigorous evaluation of plans and programs of appropriate mobility objectives. Most of these uses are already possible in conjunction with other computer analysis the Statewide Transportation Modeling System.

Finally, the application of the Statewide Transportation Modeling System proximity analysis process would allow any state agency the ability to determine the accessibility to employment, education or recreation opportunities by mode. This could lead to the effective evalution of statewide or region transportation plan and their impact on mobility.
